2 Basic model of linear regression

- Equivalent model
- Least squares method

3 Nonlinear regression

Evaluation of experimental data

Evaluation of experimental data

- Solving of chemical-engineering problems usually let us derive the model of process or phenomenon taking place in the device.
- Frequently, we are not able to identify numerical values of model parameters.

Function $\eta(x) = E(Y(x))$ defined on the domain $A \subset \mathbb{R}$ is called regression function. Regression is the relationship between E(Y(x)) – the mean value of random variable Y(x) – and the independent variable x.

Assume that we know the form of the regression function. Based on random selection, we estimate its unknown parameters:

We choose *n* values of independent variable $x_j \in A$, j = 1, ..., n, and for each x_j observe (measure) the realization (value) y_j of random variable Y_j :

$$x_j \in A, \ j = 1, \ldots, n \quad \longrightarrow \quad y_j = Y(x_j).$$

Obtained pairs of values $(x_1, y_1), \ldots, (x_n, y_n)$ are used for the estimation of unknown parameters.

Nonlinear regression

Recommended literature

Basic model of linear regression

Model of linear regression must fulfil:

1. $\eta(x)$ is a linear function of the form

$$\eta(\mathbf{x}) = \sum_{k=1}^{p} \beta_k f_k(\mathbf{x}),$$

where $f_k(x)$ are known functions, and β_k , k = 1, ..., p, unknown parameters. The function η is linear in parameters.

2. Value x_i is assigned random variable Y_i , for which it reads

$$E(Y_j) = \eta(x_j), \quad D(Y_j) = \sigma^2, \quad j = 1, \ldots, n,$$

The second equation means that the variance is independent of x_j , and thus it is constant. For example, it corresponds to the case that all realizations y_1, \ldots, y_n of random variables Y_1, \ldots, Y_n are measured with the same precision.

- **3.** Matrix $F = (f_{ij})$, where $f_{ij} = f_i(x_j)$, i = 1, ..., p, j = 1, ..., n, has the rank p. Note that the number n of pairs (x_j, y_j) must be greater than the number of unknown parameters p, precisely, it should hold true n p > 2.
- **4.** Random variables Y_1, \ldots, Y_n are not correlated, i.e.

$$\operatorname{cov}(Y_i, Y_j) = 0, \quad i, j = 1, \dots, n, \quad i \neq j.$$

Matrix notation

$$C_y = \sigma^2 E_n \,,$$

where E_n is the identity matrix of order n, C_y is the covariance matrix of variables Y_1, \ldots, Y_n .

Example A regression line, i.e. the regression function of the form $\eta(x) = \alpha + \beta x$ has the number of unknown parameters p = 2, and $\beta_1 = \alpha$, $f_1 = 1$, $\beta_2 = \beta$, $f_2 = x$.

Equivalent model

 \star

Described model in the equivalent form is

$$Y_{j} = \eta(x_{j}) + \varepsilon_{j} = \sum_{k=1}^{p} \beta_{k} f_{kj} + \varepsilon_{j}, \quad j = 1, \dots, n,$$
(1)

where values x_1, \ldots, x_n are values of nonrandom variables, values $f_{kj} = f_k(x_j)$ fulfil the 3. condition of the model. Random errors ε_j , $j = 1, \ldots, n$, and the covariance matrix C_{ε} of the random vector $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_n)$ fulfil

$$E(\varepsilon_j) = 0$$
, $j = 1, \ldots, n$, $C_{\varepsilon} = \sigma^2 E_n = C_y$.

Equation (1) reads in the matrix form

 $\overrightarrow{Y} = F^{\mathrm{T}} \overrightarrow{\beta} + \overrightarrow{\varepsilon} .$

Nonlinear regression

Least squares method

Least squares method

We find unknown parameters β_1, \ldots, β_p in described model of linear regression by least squares method. Let these estimations are b_1, \ldots, b_p , which are selection functions of random choice Y_1, \ldots, Y_n . We minimize the sum of squares of deviations from observed values y_j and their mean values $\eta_i = \eta(x_i)$, thus the sum of squares is

$$Q(\beta_1,...,\beta_p) = \sum_{j=1}^n (y_j - \eta_j)^2 = \sum_{j=1}^n \left(y_j - \sum_{k=1}^p \beta_k f_{kj} \right)^2$$

Thus estimations b_1, \ldots, b_p are found as a solution of the set of equations

$$\frac{\partial Q}{\partial \beta_k} = 0, \quad k = 1, \dots, p.$$

This system is called the system of normal equations.

Evaluation of experimental data	Basic model of linear regression	Nonlinear regression	Recommended literature
I see the management in a state of			

We can rewrite the system of normal equations for searched estimations b_1, \ldots, b_p in a lucid form

where

$$S_{ki} = \sum_{j=1}^{n} f_{kj} f_{ij}, \quad i, k = 1, ..., p,$$

$$S_{ky} = \sum_{j=1}^{n} f_{kj} y_j, \quad k = 1, ..., p.$$

Clearly $S_{ik} = S_{ki}$ for $i, k = 1, \ldots, p$.

(日) (日) (日) (日) (日) (日) (日)

Least squares method

Matrix notation: If $\overrightarrow{y} = (y_1, \dots, y_n)^{\mathrm{T}}$, $\overrightarrow{b} = (b_1, \dots, b_p)^{\mathrm{T}}$, then normal equations can be written in the form $F F^{\mathrm{T}} \overrightarrow{b} = F \overrightarrow{y}$. (2)

Assume that h(F) = p, then also $h(F F^{T}) = p$ and $F F^{T}$ is of the type $p \times p$, regular \implies exists $(F F^{T})^{-1}$, and thus from equation (2) we can express vector \overrightarrow{b} :

$$\overrightarrow{b} = (F F^{\mathrm{T}})^{-1} F \overrightarrow{y} ,$$

the vector \overrightarrow{b} is uniquely determined and its each component is a linear combination of values y_1, \ldots, y_n .

Attention! Calculation is extremely numerical unstable, see the lecture "Linear algebra".

Evaluati	on of	experin	nental	data

Nonlinear regression

< □ > < 同 > < 三 > < 三 > < 三 > < ○ < ○ </p>

Least squares method

Let a regression line goes through the beginning, $\eta(x) = ax$, then $f_j = x_j$ and $\beta_1 = a$. Denote $\overrightarrow{x} = (x_1, \dots, x_n)^T$, $F = (x_1, \dots, x_n)$. Then

$$F F^{\mathrm{T}} = (x_1, \ldots, x_n) \cdot (x_1, \ldots, x_n)^{\mathrm{T}} = \sum_{j=1}^n x_j^2 \implies (FF^{\mathrm{T}})^{-1} = \frac{1}{\sum_{j=1}^n x_j^2}.$$

Estimation of the parameter a is

$$\mathbf{a} = (\mathbf{F} \mathbf{F}^{\mathrm{T}})^{-1} \mathbf{F} \overrightarrow{\mathbf{y}} = \left(\frac{1}{\sum_{j=1}^{n} x_{j}^{2}}\right) \overrightarrow{\mathbf{x}}^{\mathrm{T}} \overrightarrow{\mathbf{y}} = \frac{\sum_{j=1}^{n} x_{j} y_{j}}{\sum_{j=1}^{n} x_{j}^{2}}$$

Least squares method

★ Example

Experiments were conducted in which ice crystals were placed into a compartment at a constant temperature (-5°C). In order to analyze the growth of the ice crystals as a function of time, the saturation of the air by water was kept constant. The experimental data points were randomized over time. The experimental data are presented in the following table, where *y* is the axial length of the crystals in microns and *x* is the time in seconds. Repeated measurements were also performed in order to examine the lack of fit. Use a straight–line model, $y = \beta_0 + \beta_1 x$ and fit it to the data.

Nonlinear regression

Recommended literature

Least squares method

The experimental data are in vector and matrix notation

$$y = \begin{bmatrix} 19\\ 20\\ 21\\ 17\\ \vdots\\ 35\\ 38 \end{bmatrix}, X = \begin{bmatrix} 1 & 50\\ 1 & 60\\ 1 & 60\\ 1 & 70\\ \vdots & \vdots\\ 1 & 170\\ 1 & 180 \end{bmatrix},$$

where *y* is $n \times 1$ vector and *X* is an $n \times p$ matrix; n = 43 is the total number of experimental points, and *p* represents the number of parameters, in this case two: β_0 , β_1 . The first column of *X* should only contain 1 in each position. The number of different *x*-positions is m = 22. As there are many repeated experiments, *m* is significantly lower than the total number of experimental points *n*. We denote n_i the number of observations for each x_i , i = 1, ..., m, and $n = \sum_{i=1}^m n_i$. The model parameters can be calculated as follows:

$$b = [\beta_0, \beta_1] = (X^T X)^{-1} X^T y = \begin{bmatrix} 14.19\\ 0.1346 \end{bmatrix}$$

We obtained the model y = 14.19 + 0.1346 x.

▲□▶▲□▶▲□▶▲□▶ □ のへの

Least squares method

★ Unbiased estimation of linear parametric function

Task We find estimation of the linear function of parameters $\vec{\beta} = (\beta_1, \dots, \beta_p)^T$. Assume a parametric function

$$\gamma = \sum_{k=1}^{p} c_{k} \beta_{k} = \overrightarrow{c}^{\mathrm{T}} \cdot \overrightarrow{\beta} ,$$

where $\overrightarrow{c} = (c_1, \dots, c_p)^T$ is known nonzero vector ($\overrightarrow{c} \neq 0$).

Statement The best estimation of linear parametric function $\vec{c}^{T} \cdot \vec{\beta}$ is a function (statistics) $g = \vec{c}^{T} \cdot \vec{b}$, where \vec{b} is the solution of normal equations. $E(g) = \gamma$, and "the best" means that the variance D(g) is minimal in the class of unbiased estimations.

Nonlinear regression

< □ > < 同 > < 三 > < 三 > < 三 > < ○ < ○ </p>

Nonlinear regression

Goal: Estimation of parameters a_1, \ldots, a_n in nonlinear empirical formulae

$$y = f(\mathbf{x}, \mathbf{a})$$
.

We will minimize the sum of squares of deviations

$$S(\mathbf{a}) = \sum_{j=1}^{m} \left(f(x^{j}, a) - y^{j} \right)^{2} = \sum_{j=1}^{m} q_{j}^{2}(a),$$

where q_j is the residuum of *j*th measured point. Denote by a^+ the point in which the sum of squares S(a) has its minimum. The value a^+ is obtained as a limit of so called minimizing sequence a^k in such a way that

$$S(a^{k+1}) < S(a^k)$$
.

Nonlinear regression

Taylor series of function *f* (neglect terms of higher order than 1):

$$f(x,a) \approx f(x,a^k) + \operatorname{grad}_a^{\mathrm{T}} f(x,a^k) (a-a^k) \quad \Longleftrightarrow$$

$$f(x, a) \approx f(x, a^k) + \sum_{j=1}^n \frac{\partial f(x, a^k)}{\partial a_j} (a_j - a_j^k).$$

Evaluate the approximation formulae

$$y - f(x, a^k) = \sum_{j=1}^n \frac{\partial f(x, a^k)}{\partial a_j} \triangle a_j^k.$$

Let $\Gamma(a)$ be the Jacobi matrix,

$$\Gamma(a) = \begin{pmatrix} \frac{\partial f(x^1, a)}{\partial a_1} & \frac{\partial f(x^1, a)}{\partial a_2} & \cdots & \frac{\partial f(x^1, a)}{\partial a_n} \\ \vdots & & \vdots \\ \frac{\partial f(x^m, a)}{\partial a_1} & \frac{\partial f(x^1, a)}{\partial a_2} & \cdots & \frac{\partial f(x^m, a)}{\partial a_n} \end{pmatrix}$$

٠

Nonlinear regression

Recommended literature

We search for a solution:

$$\triangle^+ a^k = -\left(\Gamma^{\mathrm{T}}(a^k) \, \Gamma(a^k) \right)^{-1} \Gamma^{\mathrm{T}}(a^k) q(a^k) \, ,$$

where $q = (q_1, \ldots, q_m)$. Using $riangle^+ a^k$ we calculate the next iteration

$$a^{k+1} = a^k + \lambda riangle^+ a^k \,, \quad \lambda \in (0,1) \,.$$

The starting value: $\lambda = 1$. If $S(a^{k+1}) \ge S(a^k)$, then we decrease λ .

The calculation is performed for

$$\underbrace{\Gamma^{\mathrm{T}}(a^k)\,\Gamma(a^k)}_{} \triangle^+ a^k = -\Gamma^{\mathrm{T}}(a^k)\,q(a^k)\,.$$

matrix $n \times n$

Process is stopped, if $||\triangle^+ a^k||$ is less than a required precision.
